Role:Member

- **Specific Tasks performed**

The task that was assigned to me is in the backend. The first decision of our group is just to focus on the login and register feature for the client but our leader decided to add the feature for viewing, updating, deleting, and inserting values in the inventory of our ecommerce database. So I was assigned to create a rest api for viewing products and inserting new products in the inventory. However, one of the members had trouble with her web design and so I provided a simple interface for the inventory, that file was actually just for me because I wanted to check if the server side works with the client but it was then used for our final output, Kathleen just continued the interface by providing buttons for it. I also checked the codes for web-based clients in connecting to the php files because some variables don't match with the client and server file.

- **Code Contribution**

I created 2 php files for viewing all the products and inserting new products. The inserting of product to the inventory accepts a POST method as it means of creating a new instance in the database. Then included the db_connection.php to connect to the server and access the database. After ensuring that the client and server are connected, it will now get the values from the client side and pass those values to the variables that are used for inserting to the database. There is an error handling with the values retrieved from the client, if it is not complete it will return a message of "Missing required fields". Once the process is done it will return a success message that the product was added successfully. On the other hand, the other file is for viewing the products stored in the database basically just have the same process with the inserting file its just that this time the query is just simple "select * from inventory;". This accepts a GET method and returns an error message when the server is down.

- **Challenges Encountered**

The challenges I encountered is checking the variable names if it matches to the client side so that it can pass the values correctly, also upon trying to connect to the web based client sometimes the file doesn't work immediately because the sql query has an error such as selecting columns that needs to be specific like "select *" whereas, it should be "select inventory_id" and it is really hard to identify what part we made a mistake since I am working on both the client and backend side. In addition, sometimes Xampp errors when starting so I need to fix it first so it can be accessed.

- **Contribution in solving the problem**

I always check for my groupmates if they struggle with their part and help them with tasks like debugging their code. I also figure things out by searching relevant information to understand every part of the code so that I can solve the error I encountered ensuring both client and server are connected.
